X-ray magnetic circular dichroism (XMCD) measured at $T=6$ K and $\mu_0H=5$ T on the α -phase Fe-phthalocyanine (FePc) textured thin films shows that the Fe^{2+} ions present an unusually large, highly unquenched $m_L=0.53 \pm 0.04 \mu_B$ orbital component, with planar anisotropy. The spin $m_S=0.64 \pm 0.05 \mu_B$ and the intra-atomic magnetic dipolar m_T components were also obtained. The $m_L/m_S=0.83$ ratio is the largest measured in $3d$ complexes and compounds. The origin of this unusually high orbital moment is the incompletely filled e_g level lying close to the Fermi energy. This explains the unusually large and positive hyperfine field detected by Mössbauer spectroscopy in FePc. The FePc film strong planar anisotropy inferred from XMCD experiments is fully confirmed by magnetization measurements.

I. INTRODUCTION

Magnetic coordination compounds are of high interest because they show peculiar quantum properties, that can be chemically tuned to modify their properties to be used for high density data storage. A detailed understanding of their specific magnetic interactions may suggest, for example, routes for processing and tailoring room temperature molecular ferromagnets. However, probing particular atoms within a magnetic molecule is often difficult and, therefore, information about interactions in covalently or coordination bonded magnetic molecules is largely lacking. Metal Phthalocyanines are simple model molecules for the understanding of the electronic properties of metals in complexes.¹ In spite of extensive work on them their magnetic properties are not fully understood. Therefore, unambiguous experimental determinations are the primary tools to challenge various theoretical predictions. In particular, the orbital moment is the main physical contribution to magnetic anisotropy. Consequently, discerning the mechanisms that control the expectation value of the orbital moment $\langle L_z \rangle$ is of paramount importance in mastering the properties of magnetic systems for basic and applied magnetism. X-ray magnetic circular dichroism (XMCD) is the tool of choice for such a study since it is element selective and capable of resolving the orbital and spin component of the magnetic moment.

Since the early days of quantum mechanics it was found that in solids of local low-symmetry environments the angular momentum is quenched by crystal field (CF) effects.² This was proven more recently by XMCD in Fe_8 (Ref. 3) and Mn_{12} -acetate^{3,4} molecular magnets, in which the orbital moment is negligible as a result of the $|\pm L_z\rangle$ mixing induced by the CF interaction acting on the magnetic atom. On the other hand, the spin-orbit coupling splits the CF spin degenerate levels and a nonzero orbital moment contribution appears in the magnetic ground state. Usually the orbital moment is small compared to the spin component, but a remarkable

enhancement of the orbital moment of magnetic systems was observed at film interfaces,⁵ monoatomic metal chains,⁶ nanoparticles,⁷ or very small clusters.⁸ In the limit of atomic size, that is, as atomic impurities in solids, the orbital moment may be only partially quenched, with values approaching the free atom ones.^{9,10}

In this paper, in drastic contrast to all above cases, we present a direct proof of the presence of a very large, highly unquenched orbital moment $m_L=0.53 \pm 0.04 \mu_B$ in a low-symmetry, planar Fe(II)-Phthalocyanine (FePc) molecule.

In FePc, the Fe atom has square-planar coordination with four pyrrolic N atoms. In the bulk and thin films these planar molecules form linear chains by columnar stacking. The molecule fourfold axis is tilted with respect to the crystal b axis by an angle ϕ . In the bulk form only two phases appear; the α -FePc with a tilting angle of $\phi=26.5^\circ$, and the β phase with $\phi=44.8^\circ$. The former becomes ferromagnetic below $T_C \sim 10$ K in the bulk form while the latter is paramagnetic down to liquid helium temperatures. The magnetic properties were satisfactorily interpreted in terms of an effective spin $S=1$ Fe(II) model.¹¹

II. EXPERIMENTAL DETAILS

Thin films of FePc are deposited on a smooth gold substrate with the molecule plane lying flat on the substrate plane.¹² The thin film sample in this work was prepared in an organic molecular beam epitaxy (OMBE) system. Sigma-Aldrich FePc was purified in three cycles using the temperature gradient method. The purified material was loaded into a vacuum chamber and out-gassed for several hours before deposition. The chamber pressure during the deposition was 1.2×10^{-8} Torr with the base pressure around 5×10^{-9} Torr.

In thin films grown by OMBE the molecule plane orientation is set by a proper substrate selection and the growth conditions.^{13,14} In order to obtain α -phase FePc films with

the molecule plane parallel to the sapphire substrate, first a 40 nm nominal thickness Au buffer layer was deposited at a rate of 0.3 Å/s. This buffer layer was annealed for one hour at 300 °C “in situ” to remove any water from the surface and to smoothen the Au surface. Without breaking vacuum, the FePc was deposited from a crucible set to 350 °C, while the substrate was maintained at 150 °C to increase the crystallite size. The typical growth rate was 0.9 Å/s. The FePc deposition rate was determined by means of a quartz crystal monitor before and after the deposition. The nominal thickness was then calculated by comparison to a thickness calibrated FePc sample. The FePc thickness of the investigated sample was 80 nm.

The x-ray linear polarized absorption (XLPA) and XMCD experiments were performed at the ID08 beamline of the European Synchrotron Radiation Facility (ESRF) in Grenoble. A spherical grating monochromator was used. The photon flux at the sample was 10^{12} photons per second in a 5×10^{-4} bandwidth. The energy resolution at the Fe- $L_{2,3}$ energy region is about $\Delta E/E = 5 \times 10^{-4}$. The detection technique was total electron yield. In both experiments a monochromatic x-ray beam impinges the sample with varying incidence angles γ with the normal to the substrate and the molecule plane (see inset in Fig. 2) within the range $0^\circ < \gamma < 75^\circ$. In XLPA, the light is linearly polarized while in XMCD it is right- and left-circularly polarized. The XMCD experiment was performed with $\mu_0 H = 1, 3,$ and 5 T applied magnetic field. To avoid experimental artifacts, the four combinations of field direction and circular polarization are recorded for each γ angle. The XMCD signal is the difference between absorption spectra recorded with the helicity anti-parallel and parallel to the field. In all cases, the polarization rate was well above 99%. All experiments were carried out at $T = 6$ K. No radiation damage of the sample was detected.

Magnetization measurements have been performed in a superconducting quantum interference device (SQUID) magnetometer, with the high sensitivity option, on a platelet of 2×2 mm², in the direction parallel (M_{xy}) and perpendicular (M_z) to the substrate plane, in the range 1.8 to 10 K.

III. FILM MORPHOLOGY

The θ - 2θ diffraction patterns of the FePc film deposited onto gold plated sapphire (Fig. 1) shows a pronounced (313) peak at $2\theta = 27.84^\circ$ indicating that the b axis of the molecule is perpendicular to the substrate plane. Note that the (200) Bragg peak at $2\theta = 6.8^\circ$, observed in a bulk powder pattern, is absent in the film where the molecule is deposited onto a gold surface. These two features show that the molecule planes are parallel to the substrate due to interaction between Au and the first FePc layer. This layered configuration is shown in the inset of Fig. 2. Atomic force microscopy and x-ray diffraction proved that the samples consist of textured columnar grains with a random distribution of the molecular x and y axes parallel to the substrate plane and a small mosaic spread in the z direction.¹³

In the XLPA experiments the polarization of \vec{E} is denoted as horizontal (H) and vertical (V) for parallel and perpendicular to the storage ring electron orbit plane, respectively.

FIG. 1. (Color online) θ - 2θ diffraction patterns of FePc film grown on a gold surface. The oscillations at low diffraction angles correspond to finite-size oscillations from the thin film. The inset shows an expanded view of the oscillations and the FePc (313) peak. The small peak at 26.6° is the same FePc (313) peak due to a tungsten impurity on the copper x-ray source.

Besides the x-ray diffraction measurement cited above, the XLPA measurements performed at the N K-edge at normal and grazing (75° from normal) incidence (shown in Fig. 2) confirm that the molecules lay parallel to the substrate plane. Indeed, the spectra in normal incidence with \vec{E}_H or \vec{E}_V polarization are identical, and also equal to the spectra with \vec{E}_V polarization in grazing incidence, as expected for \vec{E} lying in the molecule plane. On the other hand, the spectra with \vec{E}_H in grazing incidence has \vec{E} oriented 75° from the molecule plane, and the resulting spectra H and V in grazing incidence are very different, as shown in Fig. 2. Thus it is possible the

FIG. 2. (Color online) XLPA spectra recorded at the N K-edge with grazing angle incidence ($\gamma = 75^\circ$) at $T = 6$ K. The two spectra correspond to the H and V polarization modes: \vec{E} is either parallel to the FePc plane (V , dashed line) or forming an angle 15° with the normal to the substrate, i.e., to the FePc plane (H , full line). In accordance with Ref. 15, peaks A, B, and C are assigned to π^* resonances, and D, E, and F to σ^* ones. Inset: schematic view of sample FePc deposited on a Au film, previously deposited on sapphire. The incoming beam at grazing incidence is shown with the \vec{E} in the H and V polarization modes.

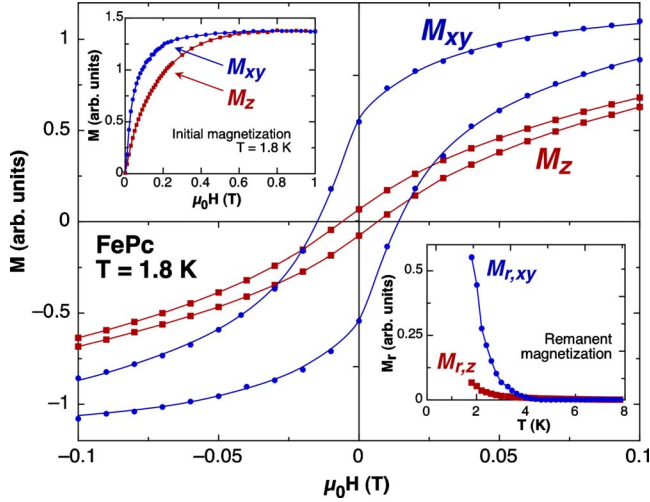

FIG. 3. (Color online) Hysteresis loop of the FePc film deposited on Au covered sapphire measured at $T=1.8$ K in the direction perpendicular (M_z) and parallel (M_{xy}) to the substrate. Insets: (a) upper left; initial magnetization at $T=1.8$ K, in the two directions; (b) lower right; remanent moment M_r as a function of temperature.

assignment of the peaks (see caption of Fig. 2) in good agreement with that proposed for NiPc deposited on Cu(110).¹⁵ The π^* resonances are found at 398.7, 400.3, and 402.3 eV and the σ^* resonances at 406.2, 409.3, and 411.6 eV. The near disappearance of the π^* resonances when \vec{E} is in the molecule plane demonstrates that the four N atoms lay in a plane parallel to the substrate.

IV. MAGNETIC CHARACTERIZATION

Initial magnetization, hysteresis cycles up to $H=5$ T and thermoremanence have been measured from $T=1.8$ K to 10 K, parallel and perpendicular to the FePc film. In Fig. 3 we show M_{xy} and M_z in the low-field regime at $T=1.8$ K. The open M_{xy} hysteresis cycle demonstrates that the film is ferromagnetic at this temperature. The coercive field is $\mu_0 H_c = 0.145$ mT. Besides, M_{xy} is higher than M_z up to 0.6 T, coalescing at this field. This feature is indicative of planar (xy) anisotropy; i.e., the easy axis of magnetization is parallel to the substrate. The initial magnetization curves; i.e., when the sample was demagnetized before the $M(H)$ experiment was done, is shown in inset (a). The M_{xy} curve has a higher slope at $H=0$ than the M_z one, again, indicating xy anisotropy. The anisotropy field can be roughly estimated, from the intercept of the M_{xy} and M_z curves, therefore, the anisotropy field is $\mu_0 H_A = 0.6$ T. The remanence magnetization dependence on temperature $M_r(T)$ is included in inset (b) of Fig. 3. M_r remains nonzero; i.e., ferromagnetic, up to $T_C \approx 4$ K, in the xy plane. Note that, the Curie temperature of this FePc film is lower than the reported $T_C=10$ K for the bulk α -FePc.¹¹ This decrease in T_C could be expected as a size effect due to the reduced (80 nm) thickness of the film. The hysteresis curves at 6 K have no open loops (not shown), but still $M_{xy} > M_z$ up to 0.6 T, so the xy anisotropy remains in the paramagnetic region near T_C . Our XMCD measurements performed at $T=6$ K, were, therefore, per-

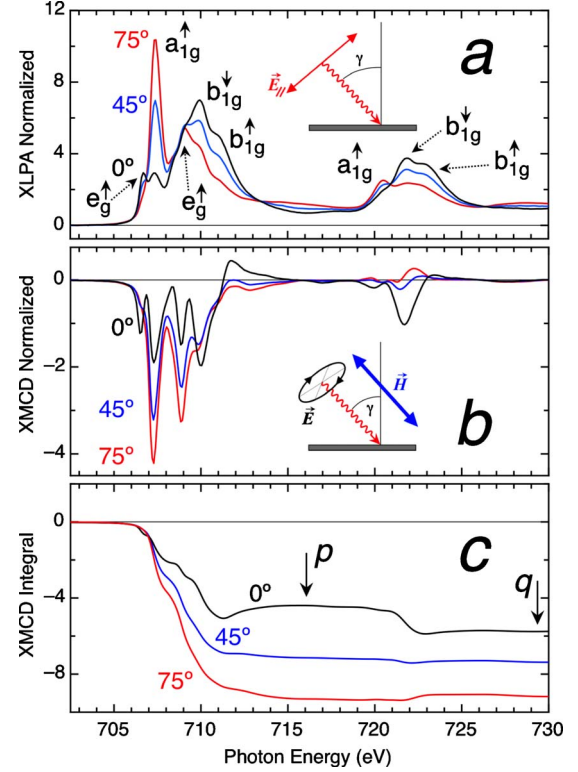

FIG. 4. (Color online) (a) normalized XLPA, (b) XMCD spectra, and (c) integrated XMCD area at the Fe $L_{2,3}$ edges on FePc at $T=6$ K for incidence angle $\gamma=0^\circ, 45^\circ,$ and 75° . In the XMCD experiment, the applied field ($\mu_0 H=5$ T) and the helicity of the beam are parallel for every γ . The arrows indicate the higher limit of the p and q integrals.

formed in the paramagnetic phase of the material. The main conclusion of this section is that the FePc film has magnetic planar anisotropy at low temperatures.

V. X-RAY SPECTROSCOPY RESULTS

Panels *a* and *b* of Fig. 4 display, respectively, selected normalized XLPA and XMCD spectra measured at the $L_{2,3}$ Fe edges. In XLPA (panel *a* of Fig. 4) the absorption intensity is proportional to the number of empty valence states in the direction of the electric field \vec{E} ,¹⁶ which is parallel to the molecule plane for $\gamma=0^\circ$ and nearly perpendicular to it for grazing incidence ($\gamma \approx 90^\circ$). Since there is a random distribution of molecules in the xy plane, the spectra are averaged over all azimuthal angles, while all molecules have a (nearly) common z . XMCD (panel *b* of Fig. 4) provides information on the polarized magnetic moment per Fe atom of the initial state.

The electronic ground state has been proposed to be 3E_g ,¹⁷⁻²⁰ among others. In the following, we show that our experimental results do support this assignment.

Indeed, taking into account the corresponding 3E_g molecular orbital level scheme (shown in Fig. 5), the e_g^5 level splitting explained in Ref. 19 (see below), and the sign of the XMCD signals, several features of the XLPA spectra can be assigned.

FIG. 5. Spin split molecular orbital energy level scheme for FePc (Ref. 17). For clarity, only the states with a relevant component of $3d$ weight ($w_{3d} > 0.05$) have been included. Note also the global change in spin sign with respect to Ref. 17.

The Fermi energy (E_F) is taken as the energy of the maximum slope of the upturn at the L_3 edge. The L_3 spectrum ($2p_{3/2} \rightarrow 3d$ transitions) shows a first peak at 706.4 eV, which may be ascribed to the e_{1g}^{\uparrow} empty level, with mixing of the a_{1g}^{\uparrow} level. This sets the lowest unoccupied molecular orbital (LUMO) at energy 0.3 eV above E_F . The next most intense peak at 707.3 eV with $\vec{E} \parallel z$ ($\gamma = 75^\circ$), nearly disappears when $\vec{E} \parallel x, y$ ($\gamma = 0^\circ$), and therefore it may be identified with a transition to the $d_{3z^2-r^2}$, i.e., the empty antibonding excited level a_{1g}^{\uparrow} (see Fig. 5) lying 0.93 eV above E_F .

On the other hand, at the high energy side of the L_3 spectra a triplet of peaks can be identified. The leftmost peak at 708.9 eV does not depend on γ , and is assigned to an e_{1g}^{\uparrow} state in the minority antibonding states stemming from hybridization with the π ligand orbitals (2.57 eV): The two on the right side (709.8 and 711.7 eV) reduce their intensity when $\vec{E} \parallel z$ and may be indexed as due to the $d_{x^2-y^2}$ states at the empty majority b_{1g}^{\downarrow} (3.52 eV) and minority b_{1g}^{\uparrow} antibonding states (4.64 eV), respectively. The L_2 edge spectra ($2p_{1/2} \rightarrow 3d$ transitions) are less resolved. However, by comparison with the L_3 edge spectra, considering their relative energies and angle dependences, the left one can be assigned to the a_{1g}^{\uparrow} excited state and the two higher energy ones to the ($d_{x^2-y^2}$) b_{1g}^{\downarrow} and b_{1g}^{\uparrow} antibonding states. A more detailed description of the XLP spectra requires a multiplet calculation, which is beyond the scope of this paper.

Information on the orbital and spin components of the magnetic moment of the absorbing atom projected along the field direction for a given incidence angle γ can be obtained from the sum rules^{21,22}

$$\frac{m_L(\gamma)}{\mu_B} = -\frac{2n_h}{r} \int (\Delta\mu_{L_3} + \Delta\mu_{L_2}) dE, \quad (1)$$

$$\frac{m_S^{\text{eff}}(\gamma)}{\mu_B} = -\frac{3n_h}{r} \int (\Delta\mu_{L_3} - 2\Delta\mu_{L_2}) dE, \quad (2)$$

where the XMCD at the $L_{2,3}$ edges is $\Delta\mu_{L_{2,3}} = \mu_{L_{2,3}}^- - \mu_{L_{2,3}}^+$, being $\mu_{L_{2,3}}^-$ and $\mu_{L_{2,3}}^+$ the absorption measured with left (-)

and right (+) circularly polarized light. n_h is the number of holes above the Fermi energy, which has been calculated for FePc as $n_h = 2.669$.¹⁷

In the following paragraphs the data analysis for $T = 6$ K and $\mu_0 H = 5$ T is shown in detail. The analysis for $\mu_0 H = 1$ and 3 T are analyzed likewise. After removal of the contributions from transitions to the continuum by subtraction of two arctangent functions centered at the L_3 and L_2 edges and $2/3$ and $1/3$ amplitude, respectively, r is calculated as $r = \int (\mu^+ + \mu^- + \mu^0) dE$, the integrated spectrum for the unpolarized radiation. $\frac{1}{2} \int (\mu^+ + \mu^-) dE = I_{L_2} + I_{L_3}$ is the integrated unpolarized x-ray absorption white-line intensity. μ^0 has been approximated by $\frac{1}{2} (\mu^+ + \mu^-)$.

In Fig. 4(c) the values of the integrated XMCD, $p = \int (\Delta\mu_{L_3}) dE$ and $q = \int (\Delta\mu_{L_3} + \Delta\mu_{L_2}) dE$, with upper integration limits at the respective arrows, have been depicted. The orbital sum rule [Eq. (1)] directly yields the orbital moment component, $m_L(\gamma) = -\langle L_z \rangle(\gamma) \mu_B / \hbar$. From the spin sum rule [Eq. (2)] and the relation $m_S^{\text{eff}}(\gamma) = m_S - 7m_T(\gamma)$ one obtains the isotropic spin moment, $m_S = -2\langle S \rangle \mu_B / \hbar$, and the intra-atomic magnetic dipolar component, $m_T(\gamma) = \langle T_\gamma \rangle \mu_B / \hbar$.

The measured XMCD magnitude with H parallel to the beam direction and incidence angle γ furnishes the projection of the Fe magnetic moment along the direction of the applied field, $m(\gamma) = \vec{H} \cdot \vec{m} / H$. The FePc molecule symmetry may be approximated to D_{4h} , therefore the fourfold axis may be taken as the principal axis, z , with the two binary axes x and y assumed identical.

In the case of a molecule lying flat on the substrate, and the x axis at an angle α with respect to a fixed reference axis parallel to the substrate, the measured magnetic moment can be decomposed into two terms:

$$m(\gamma) = m^z \cos^2 \gamma + (m^x \sin^2 \alpha + m^y \cos^2 \alpha) \sin^2 \gamma. \quad (3)$$

Due to the random distribution of the molecular axes parallel the substrate, averaging α between 0 and 2π one obtains

$$m(\gamma) = m^z \cos^2 \gamma + m^{xy} \sin^2 \gamma, \quad (4)$$

where we have defined $m^{xy} = (1/2)(m^x + m^y)$, the mean of the magnetization of the molecule in the x and y axes.

The magnetic moment m is decomposed into its orbital component

$$m_L(\gamma) = m_L^z \cos^2 \gamma + m_L^{xy} \sin^2 \gamma \quad (5)$$

and the effective spin component

$$m_S^{\text{eff}}(\gamma) = m_S - 7(m_T^z \cos^2 \gamma + m_T^{xy} \sin^2 \gamma). \quad (6)$$

In D_{4h} symmetry the diagonal tensor components fulfill the relation $\sum_{i=x,y,z} T_{ii} = 0$, therefore $(m_T^z + 2m_T^{xy}) = 0$ and only four moment components in Eqs. (5) and (6) are independent. In particular, we measured XMCD at the so-called *magic angle* $\gamma^* = 54.7^\circ$ (Ref. 23) for which $2 \cos^2 \gamma^* = \sin^2 \gamma^*$. At the incidence angle γ^* the intra-atomic dipolar contribution cancels for the D_{4h} symmetry, giving a direct measure of m_S .²³

In Fig. 6 the m_L and m_S^{eff} obtained at $T = 6$ K and $\mu_0 H = 5$ T from the sum rules as a function of γ are shown. The excellent fitting of the experimental results to Eqs. (5) and

FIG. 6. (Color online) m_L (\square) and m_S^{eff} (\bullet), as determined from the XMCD spectra at $T=6$ K and $\mu_0 H=5$ T. The lines show the fits to Eqs. (5) and (6).

(6) is also presented in Fig. 6. The four adjustable parameters are collected in Table I. In Fig. 7 the magnetic moments m_L^{xy} , m_S , and m^{xy} for $\mu_0 H=1, 3$, and 5 T are depicted together with the SQUID magnetization measurements at $T=6$ K, scaled to match the XMCD data. It is evidenced that at $\mu_0 H=5$ T the magnetization is near saturation.

The value of the isotropic spin component $m_S = 0.64 \pm 0.05 \mu_B$ resulted from the fit agrees exactly with the direct determination of m_S from the application of the effective spin sum rule at the γ^* magic incidence angle. The orbital moment is anisotropic, being largest when the applied field is parallel to the xy molecule plane, confirming our magnetization results. Its value is $m_L^{\text{xy}} = 0.53 \pm 0.04 \mu_B$. In spite of the applied approximations, and the inherent experimental uncertainty, the existence of an extraordinarily large, highly unquenched orbital moment in FePc is proven beyond doubt. This fact also explains the Mössbauer spectroscopy (MS) as a function of field measurements, which found the highest hyperfine field of positive sign ever measured on an Fe(II) ion ($B_{\text{hf}} = 66.2$ T).¹⁹ Indeed, this requires the existence of a large orbital moment to explain the field dependence of the low temperature MS sextets, in excellent agreement with our result.

The ratio $m_L^{\text{xy}}/m_S = 0.83$ is the largest reported on $3d$ ions in compounds or molecular systems. The large value of the orbital moment $m_L^{\text{xy}} = 0.53 \mu_B$ is comparable to that found for individual molecules of $\text{O}_2\text{-Fe}(\text{TPA})_4$ deposited on a Cu surface,²⁴ where also xy anisotropy was found. However, in the $\text{O}_2\text{-Fe}(\text{TPA})_4$ case it is argued that the interactions with the surface play an important role in the magnetic properties, in contrast with our FePc thin layer, where that interaction is negligible in comparison with the intermolecular interaction. Besides, such a large orbital moment ($m_L^{\text{xy}} = 0.53 \mu_B$) has also been found in V_2O_3 ,²⁵ but in this case the ratio m_L/m_S

TABLE I. The four adjusted magnetic moment parameters (in units of μ_B), obtained from the fit of the XMCD sum rule results (see Fig. 6) to Eqs. (5) and (6), and the calculated orbital to spin moment ratio.

m_L^z	m_L^{xy}	m_S	m_T^z	m_L^{xy}/m_S
0.29(5)	0.53(4)	0.64(5)	0.074(5)	0.83(4)

FIG. 7. (Color online) m^{xy} (\blacklozenge), m_L^{xy} (\square), and m_S (\bullet) as a function of field of the FePc film, as determined from XMCD measurements (see text). Magnetization versus field at $T=6$ K (\blacksquare), measured parallel to the substrate plane and scaled to m^{xy} , deduced from XMCD (see text and Table I for details). Dotted lines are guides to the eye calculated by scaling the magnetization curve.

approximately 0.3 is significantly smaller than that found in FePc.

VI. DISCUSSION

The XMCD data shows that the FePc molecules have magnetic xy anisotropy. Due to the textured character of the studied sample, with the molecule planes parallel to the substrate, this microscopic anisotropy is translated into a macroscopic xy anisotropy, which is manifest in the magnetization measurements in parallel and perpendicular directions to the substrate. This result is quite unexpected since $\alpha\text{-FePc}$ had been reiteratively described as an Ising system, with the moment perpendicular to the molecule plane.¹⁹ Of course, the FePc film has a different molecular stacking than $\alpha\text{-FePc}$, but the molecule anisotropy would be expected to be similar, if not the same. A quite reasonable possibility is that in the bulk the molecular anisotropy axis is xy , but since our previous work on $\alpha\text{-FePc}$ was performed on powder samples, where the anisotropy is averaged in all directions, we were misled to propose the molecule z axis as the magnetic easy axis. Another possibility is that the molecule moment in the z direction is not negligible ($m_z/m_{xy} \approx 0.5$), so that the averaging procedure we applied to describe the Mössbauer experiments of $\alpha\text{-FePc}$ are still valid as the xy components would cancel out. At any rate, a very low temperature diffraction experiment would be desirable to determine the magnetic structure of the ferromagnetic bulk $\alpha\text{-FePc}$, to sort out its magnetic structure. As to the FePc textured film, to our knowledge, it is beyond the experimental possibility up to date to determine its magnetic ordered structure.

The x-ray absorption spectra of powdered samples has been studied experimentally earlier. In Ref. 26 two configurations were proposed for the electronic ground state: a quintet 5A_1 or a triplet 3E , but it could not be concluded unambiguously, which was most appropriate. In Ref. 27 the authors conclude by means of multiplet calculations that the

FIG. 8. (Color online) Experimental absorption spectra (red full lines) compared to theoretical predictions from Ref. 17 (dotted blue lines) of FePc at the $L_{2,3\text{Fe}}$ edges, for normal incidence, $\gamma=0$. (a) XAS spectra; (b) XMCD spectra. Both panels share the same (arbitrary) units.

ground state configuration is 3E , under lower symmetry than D_{4h} . They mention that this configuration confirms the 3E proposed earlier from Mössbauer experiments,¹⁹ or from theoretical density functional theory (DFT) calculations on the FePc isolated molecule.¹⁷ In fact, the empty state configuration given in Ref. 27 propose the existence of holes in b_1 , b_1 , b_2 , and e states (in C_{4v} symmetry), while from the present XLPA measurements on textured FePc sample, the proposed configuration has holes in the b_{1g} , b_{1g} , a_{1g} , and e_g states in D_{4h} symmetry. Thus, there is a discrepancy whether the a_1 (a_{1g}) or b_2 (b_{2g}) is the level yielding the peak at 707.3 eV. The selection rule applied to assign that peak actually excludes the possibility that it is due to a b_2 state since in that case the peak should have highest intensity in normal incidence ($\vec{E}\parallel x,y$ plane) and zero or nearly zero for grazing incidence, contrary to our observation. In view of this argument, we propose that the ground state configuration is the triplet 3E_g type a , proposed earlier as deduced from x-ray diffraction¹⁸ and Mössbauer measurements.^{19,20}

The experimental XANES and XMCD spectra are shown in Fig. 8 together with the calculated ones in Ref. 17. For comparison, we note that in that work the energies of the excitations are given with respect to the first, leftmost peak. Instead, in the present work we take as zero energy that of the Fermi level determined as the energy of maximum slope in the low energy tail of L_3 or L_2 edges, respectively. Both the experimental and calculated XANES spectra show two lines in the low energy tails of the $L_{2,3}$ edges. The first peak is interpreted in this work as the excitation of 0.3 eV to the hole in the spin-orbit split e_g^\uparrow level, while it was taken as the reference of zero energy at the e_g^\uparrow level in Ref. 17. The second peak corresponds to the a_g^\uparrow excited level of the minority spin states, which increases its intensity with increasing γ . The most intense peaks at the right of the L_3 spectra were

ascribed in Ref. 17 from right to left, to b_{1g}^\uparrow , b_{1g}^\downarrow , and e_g^\downarrow states, at 2.99, 1.96, and 1.24 eV, respectively. Our experimental spectrum resembles the predicted one, with energies 4.64, 3.52, and 2.57 eV, respectively. The two b_{1g} peak intensities decrease for increasing γ , as predicted. The peak at 2.57 eV would be assigned to the e_g^\uparrow state, which stems from the hybridization with the ligand π_g orbital, according to the calculated level scheme. The mentioned difference in reference energy accounts partially to the different results in the excitation energies, but the approximations done in that *ab initio* calculation are the cause of the larger difference in the high energy excitations.

Another DFT calculation of the electronic structure of FePc,²⁸ contrasted to ultraviolet photoemission spectroscopy (UPS) experiments, proposes rather a ${}^3B_{2g}$ or ${}^3A_{1g}$ ground state electronic configurations, and disregard the 3E_g ones. However, these configurations do not allow by symmetry the large orbital moment found, since the orbital degeneracy originated at the e_g level disappears. This result is in contrast with our results and with the previously discussed DFT calculations.¹⁷ New calculations of XAS, XLPA, and XMCD, including angle dependence, are necessary to solve unambiguously this question, though it seems that FePc has a 3E_g ground state configuration is a quite robust result.

The present results showing a largely unquenched orbital moment are in qualitative agreement with the following model. The Fe(II)- N bond is time-shared between the two pairs of opposite N atoms, giving rise to orbital degeneracy of the e_g ($d_{xz}d_{yz}$) level. In the spin-split ligand-field energy level scheme for FePc supported by our experiments (Fig. 5), an unoccupied state is available at the $e_g(d_{xz}d_{yz})$, and a second at the $a_{1g}(d_{3z^2-r^2})$ level. The spin-up electron on the e_g level may occupy either the d_{xz} or the degenerate d_{yz} orbital component of the doublet. The hole-hole interaction between the $e_g(d_{xz}d_{yz})$ and the $a_{1g}(d_{3z^2-r^2})$ holes and the spin-orbit coupling split the degenerate states into three doublet states, with the ground state being the doublet with $\langle L_z \rangle = \pm \hbar$. The orbital moment of the free Fe(II) is, therefore, only partially quenched. A second-order perturbation spin-orbit or crystal field perturbation (for example, a lowering of symmetry by a small distortion of the molecule to D_{2h}) would split this doublet, therefore yielding to an occupied and an unoccupied e_g level with a_{1g} mixing. The resulting ground state is that of a partially quenched orbital moment.¹⁹

It is very interesting to note that in recent electron energy-loss spectroscopy (EELS) experiments on thin free-standing films of FePc, a low energy excitation from the a_{1u} ligand states into the Fe $3d$ (e_g) states have been observed.²⁹ These are hybridized states with the ligand e_g states and a necessary condition for its observation is that the Fe $3d$ (e_g) are not fully occupied. This experimental observation is regarded by those authors as proof of the soundness of our model to explain the large orbital moment found, first proposed in Ref. 19.

The dipolar term has a strong contribution to m_S^{eff} in this case. Since $m_T(\gamma) = \hat{T}_\gamma \mu_B / \hbar$ one obtains $T_{xx} = T_{yy} = -0.037\hbar$, and therefore, $T_{zz} = 0.074\hbar$.²³ These are quite large values, comparable to the calculated value of Fe²⁺ in a surface site,³⁰ and is related to the planar symmetry of the ligand field in FePc.

With the experimentally determined values of m_L^{xy} , m_L^z , and m_T^z it is possible to derive an estimation of the magnetic anisotropy energy originating from spin-orbit coupling by means of the expression

$$\Delta E_{SO} = -\frac{G}{H} \left\{ \frac{\xi_{3d}(m_L^z - m_L^{xy})}{4\mu_B} + \frac{\xi_{3d}^2 \left[\left(\frac{21}{2} \right) \left(\frac{3}{2} \right) m_T^z + A \right]}{\Delta E_{ex}\mu_B} \right\}, \quad (7)$$

where $G/H \approx 0.2$ for transition metals, $\xi_{3d} = 0.05$ eV for Fe,³¹⁻³⁶ and $\Delta E_{ex} = 1$ eV is the energy shift between the majority and minority states. This value is extracted from our spectroscopic results as the energy difference between the b_{1g} minority and b_{1g} majority energy levels. The term A is independent of the spin direction and may be considered as negligible. The first term corresponds to the anisotropy originating from the difference in orbital moment between the perpendicular and parallel directions to the substrate plate (thus of orbital origin), and the second term from the intra-atomic dipolar term, describing the anisotropy in the spin density. Substituting, one obtains: $\Delta E_{SO} \approx +6.0 \times 10^{-4} - 5.3 \times 10^{-4} = 7 \times 10^{-5}$ eV. Thus, the orbital term and the dipolar term are of the same order of magnitude and are competing with each other. The sign is positive, thus favoring xy anisotropy. Since the anisotropy field was estimated as $\mu_0 H_A = 0.6$ T, the anisotropy (volume) constant can be evaluated as $|K_1| = \mu_0 H_A M_s / 2$, yielding $K_1 = -2.2 \times 10^3$ J/m³, or $\Delta E_{SO} = 2.1 \times 10^{-5}$ eV/at, assuming the specific volume of Fe atoms as $v = 1.48 \times 10^{-28}$ m³, as in α -FePc. The experimental value is of the same order of magnitude as the theoretical estimation from Eq. (7), although somewhat lower. Of course, Eq. (7) is just a rough approximation since the original model is derived for a fully occupied majority band, and a completely empty minority band, which is not our case, but it justifies qualitatively our finding of xy anisotropy in FePc.

VII. CONCLUSION

The FePc film deposited on a smooth Au substrate, with the molecule planes lying flat on the substrate plane, as demonstrated by x-ray diffraction and XLPA measurements on the N K-edge, has xy anisotropy, as shown by magnetization measurements below the magnetic ordering temperature $T_C = 4$ K. Besides, the XLPA angle-dependent spectra at the $L_{2,3}$ Fe edges have been indexed in terms of the 3E_g type a electronic configuration.

From the XMCD measurements at the $L_{2,3}$ Fe edges, the xy anisotropy is also demonstrated and an unusually large orbital moment in FePc molecule is found. This happens, in spite of the low symmetry of the molecule, because of the large orbital degeneracy caused by the time sharing of the two opposite Fe–N bond pairs. Similar behavior may be expected in other very interesting Fe²⁺ planar molecules, such as in α -Fe OETA-Porphyrin, where also a very large hyperfine field ($B_{hf} = 62.1$ T) has been measured.³⁷

To obtain a large orbital moment the specific conditions found are: (a) planar symmetry yielding to a level scheme, in increasing energy, b_{2g} , e_g , a_{1g} , and b_{1g} , (b) the electron occupancy of these levels leaves the e_g incompletely filled, thereby creating orbital degeneracy, and (c), a second-order perturbation rendering as ground state a singlet with partially quenched, but high, orbital moment. These conditions are fulfilled by Fe(II) in the FePc molecule. One can view this as a general result, and may help in the search of new molecules with high magnetic anisotropy.
